

OPTICAL WAVEGUIDE LENS AND METHOD OF FABRICATION

BACKGROUND OF THE INVENTION

1. Field of the Invention

The present invention relates generally to optical waveguide lenses used for collimating or focusing a light beam traversing free space in an optical component, and particularly to a spherical lens formed on the distal end of an optical fiber.

2. Technical Background

Advances in optical communications have generated significant need for optical components which involve light being transmitted to or from an optical fiber through free-space to interact with or pass through one or more optical device. A wide variety of passive and active optical devices exist, some simple examples including thin-film filters or birefringent elements, and some of the more complex being large scale three-dimensional switch fabrics. Other uses for free-space optical components include injecting light from a laser diode into an optical fiber, transmitting light through free-space from one optical fiber to another (such as an amplifier fiber), or projecting light from an optical fiber to a detector.

In optical components utilizing free-space transmission of light (sometimes called micro-optic components), the light beam is often either expanded and collimated into approximately parallel rays from the exposed end of an optical fiber, or conversely focused from an expanded beam into a narrower beam capable of being injected into the end of the optical fiber at a desired angle of incidence. While other functions may be performed on the light beam exiting or entering an optical fiber, collimating and

focusing are the functions which are most commonly encountered in micro-optic components.

In order to accomplish the collimating or focusing functions within the specifications required for optical communications, cylindrically-shaped gradient-index (GRIN) lenses employing a graduated radial refractive index profile have become the most prevalent conventional alternative. However, commercially-available GRIN lenses are expensive, difficult to manufacture, and present certain disadvantages in assembling, aligning, and tuning the optical components.

Several other approaches to fabricating collimating or focusing lenses for optical components are known. Axial GRIN lenses, molded polymer and glass lenses having spherical and aspherical lens surfaces, composite or complex lens elements, optical fibers having integral lenses formed by processes such as thermal expansion or diffusion, and ball lenses are among the many alternatives.

One approach to producing a larger-diameter collimating or focusing lens attached to the end of an optical fiber involves fusing a cylindrical glass rod onto the end of the optical fiber, and heating the rod above its softening point so that surface tension forms the viscous melted glass into a spherical lens. The resulting lens will usually have a cylindrical section of equal diameter with the optical fiber, and a spherical section of larger diameter. A light beam exiting the end of the optical fiber will expand in the cylindrical portion of the lens at a rate dependent on the refractive index of the material, and continue expanding through the spherical portion until refracted at the interface between the spherical lens surface and the surrounding air. The expanded or collimated beam is approximated as parallel rays at an operating distance from the lens surface, but in fact has a region of progressively decreasing beam waist as the initial displacement from the lens surface increases. Spherical fiber lenses fabricated according to this technique have provided beam expansion by Gaussian diffusion from the 10 μm core of standard 125 μm diameter single-mode optical fiber to an expanded beam diameter of approximately 80 μm at the exit face of a lens having a 200 μm radius of curvature, with the beam converging to an approximately 30 μm beam diameter at the beam waist located .65 mm from the lens surface. For spherical fiber lenses having up to about 350 μm radii of curvature, beam diameters of up to about 120 μm could be achieved at a beam waist located

approximately 4.5 mm from the lens surface, implying a 9 mm separation between a pair of collimating lenses having an optical device disposed in between within an optical component.

5

SUMMARY OF THE INVENTION

One aspect of the present invention is an optical-waveguide lens for collimating or focusing a light beam comprising an optical waveguide and a lens member connected to and extending from the end of the optical waveguide, wherein the lens member has a throat portion whose cross-sectional dimension is substantially greater than the diameter of the optical waveguide, and a generally spherical lens portion.

10

In another aspect, the present invention is an optical waveguide lens including an optical waveguide and a generally spherical lens member, wherein the mode field diameter or beam diameter of a light beam projected from the spherical lens member is greater than 100 μm measured at a displacement from the surface of the spherical lens member corresponding to the beam waist.

15

A further aspect of the present invention is an optical waveguide lens including an optical waveguide and a generally spherical lens member attached to the optical waveguide, the generally spherical lens being fabricated from a glass having a softening point less than that of the core of the optical waveguide.

20

In another aspect, the present invention is an optical waveguide lens including an optical waveguide and a generally spherical lens member attached to the optical waveguide, the generally spherical lens being fabricated from a borosilicate glass, and particularly a 4 mole percent borosilicate glass.

25

A further aspect of the present invention is a method for fabricating an optical waveguide lens comprising the steps of providing an optical waveguide, providing a lens blank defining a cross-sectional dimension substantially greater than the diameter of the optical waveguide, fusing the lens blank to the optical waveguide, heating a portion of the lens blank above its softening point, applying tension to the lens blank until it separates to form a segment having a tapered distal end connected to the optical waveguide, and heating the tapered distal end of the lens blank above its softening point such that a spherical lens portion is formed in alignment with the axis of the

30

optical waveguide and through which the light beam is transmitted, the optical waveguide lens defining a throat portion disposed between the optical waveguide and the spherical lens portion whose cross-sectional dimension is substantially greater than the diameter of the optical waveguide and substantially less than the diameter of the spherical lens portion.

Another aspect of the present invention is a method for using an optical waveguide lens to fabricate an optical component comprising the steps of providing an optical fiber lens including an optical waveguide, a throat portion whose cross-sectional dimension is substantially greater than the diameter of the optical waveguide, and a generally spherical lens portion whose diameter is substantially greater than the cross-sectional dimension of the throat portion, positioning the optical fiber lens relative to the optical device such that the light beam propagates either from the optical fiber lens to the optical device or from the optical device to the optical fiber lens, or both and securing the optical fiber lens relative to the optical device.

A further aspect of the present invention is method for fabricating an optical waveguide lens assembly comprising the steps of providing an optical waveguide, providing a ferrule defining a bore and an end surface, inserting the optical waveguide through the bore such that a segment of the distal end of the optical waveguide is exposed, forming a lens member including a generally spherical portion on the distal end of the optical waveguide, retracting the optical waveguide through the bore at least until a portion of the lens member contacts the end surface of the ferrule, and securing the optical waveguide in position relative to the ferrule.

Another aspect of the present invention is a method for fabricating a plurality of generally spherical lenses each having a mounting post extending therefrom comprising the steps of providing an elongated stock of a glass material from which the plurality of spherical lenses are to be formed, forming a spherical lens on the distal end of the elongated stock by heating the glass material above its softening point such that a portion of the elongated stock forms the spherical lens due in part to a surface tension of the glass material, separating the spherical lens and a segment of the elongated stock connected thereto from a remaining portion of the elongated stock such that the segment connected to the spherical lens forms the mounting post for the spherical lens,

and repeating the forming step and the separating step to fabricate the plurality of spherical lenses each having the mounting post extending therefrom.

A further aspect of the present invention is a pump multiplexer for combining a first optical signal from a pump light source with a second optical signal from a transmission waveguide into a common optical waveguide comprising a first input waveguide and a second input waveguide each having an end optically coupled to respective ones of the pump light source and the transmission waveguide, a birefringent material disposed so that the ends of the first and second input waveguides confront a first face of the birefringent material, and an output waveguide optically coupled to the common optical waveguide and confronting a second face of the birefringent material, wherein at least one of the first input waveguide, the second input waveguide, or the output waveguide have a generally spherical lens formed on the end thereof.

Additional features and advantages of the invention will be set forth in the detailed description which follows, and in part will be readily apparent to those skilled in the art from that description or recognized by practicing the invention as described herein, including the detailed description which follows, the claims, as well as the appended drawings.

It is to be understood that both the foregoing general description and the following detailed description are merely exemplary of the invention, and are intended to provide an overview or framework for understanding the nature and character of the invention as it is claimed. The accompanying drawings are included to provide a further understanding of the invention, and are incorporated in and constitute a part of this specification. The drawings illustrate various embodiments of the invention, and together with the description serve to explain the principles and operation of the invention.

BRIEF DESCRIPTION OF THE DRAWINGS

Figure 1 is a micrograph showing a first embodiment of the optical waveguide lens of the present invention in which an individual optical waveguide is fused to a lens member having a throat portion and a spherical lens portion, the throat portion having a cross-sectional dimension substantially greater than the diameter of the optical waveguide;

Figure 2 is a micrograph showing an alternate embodiment of the optical waveguide lens of the present invention in which a pair of spaced-apart optical waveguides are fused to the lens member, the throat portion similarly having a cross-sectional dimension substantially greater than the diameter of each of the optical waveguides or their combined diameters;

Figure 3 is a micrograph showing an alternate embodiment of the optical waveguide lens of the present invention in which a pair of parallel adjoining optical waveguides are fused together along a restricted-diameter portion and optically coupled to the lens member, the throat portion similarly having a cross-sectional dimension substantially greater than the diameter of the optical waveguides or the restricted-diameter portion;

Figure 4 is a micrograph showing an optical waveguide lens of the embodiment depicted in Figure 1 in which the optical waveguide has a diameter of approximately 125 μm , the throat portion has a cross-sectional dimension of approximately 200 μm , the spherical portion of the lens member has a diameter of approximately 400 μm , and the mode field diameter of the projected beam is approximately 50-100 μm measured at the beam waist;

Figure 5 is a micrograph showing an optical waveguide lens of the embodiment depicted in Figure 1 in which the optical waveguide has a diameter of approximately 125 μm , the throat portion of the lens member has a cross-sectional dimension of between 200-250 μm , the spherical portion of the lens member has a diameter on the order of 1 mm, and the mode field diameter of the projected beam is approximately 100-250 μm measured at the beam waist;

Figure 6 is a micrograph showing an optical waveguide lens of the embodiment depicted in Figure 1 in which the optical waveguide has a diameter of approximately 125 μm , the throat portion of the lens member has a cross-sectional dimension of between 200-300 μm , and the spherical portion of the lens member has a diameter on the order of 2 mm, and the mode field diameter of the projected beam is greater than 300 μm measured at the beam waist;

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

Reference will now be made in detail to the present preferred embodiments of the invention, examples of which are illustrated in the accompanying drawings. Wherever possible, the same reference numbers will be used throughout the drawings to refer to the same or like parts. An exemplary embodiment of the optical waveguide lens of the present invention is shown in Figure 1, and is designated generally throughout by reference numeral 10.

In accordance with the invention, referring to Figures 1-6 it may be seen that the present invention for an optical waveguide lens 10 includes an optical waveguide 12, a

lens member 14 having a throat portion 16 and a generally spherical lens portion 18. The lens member 14 is attached to the optical waveguide 12 at a junction 20 formed by fusion splicing the lens member 14 to the optical waveguide 12 according to the process described further below.

Figure 1 depicts an optical waveguide lens 10 in which a conventional optical waveguide 12 (such as a single-mode optical fiber, multi-mode optical fiber, polarization-maintaining optical fiber, an optical fiber having a circular or noncircular cross-section, or a dual- or multi-core optical fiber) is optically coupled to a throat portion 16 of the lens member 14, the throat portion 16 having a cross-sectional dimension substantially greater than the diameter of the optical waveguide 12, and a spherical lens portion substantially greater in diameter than the throat portion.

Figure 2 depicts an alternate embodiment of the optical waveguide lens 10 in which a pair of optical waveguides 12 are optically coupled to the throat portion 16 of the lens member 14 at distinct radial locations on the rear face 22 of the throat portion 16, and the optical waveguides 12 are disposed extending generally parallel to one another and spaced apart from one another along the length thereof adjacent to the lens member 14. The throat portion 16 has a cross-sectional dimension which is substantially greater than the diameter of either of the optical waveguides 12, and also substantially greater than the combined diameters of the two optical waveguides 12.

Figure 3 depicts an alternate embodiment of the optical waveguide lens 10 in which a pair of optical waveguides 12 are fused together at a restricted-diameter portion 24 directly adjacent or closely proximate to the junction 20 with the lens member 14, and are each optically coupled to the throat portion 16 of the lens member 14 with the cores of the optical waveguides substantially closer than the case of the two radially-displaced optical waveguides 12 shown in Figure 2. The throat portion 16 has a cross-sectional dimension which is substantially greater than the diameter of the restricted-diameter portion 24 of the fused optical waveguides 12 or the diameters of the individual optical waveguides 12. The optical waveguides 12 may be fused or connected to one another along their lengths, or may diverge from one another at a point remote from the lens member 14. Alternately, a separable core optical fiber having two or more interconnected but physically-separable core and cladding structures may be utilized as the optical waveguides 12. The spacing of the cores of the

optical waveguides 12 in the restricted-diameter region 24 may be controlled to less than the outside diameter of a single optical waveguide 12.

Referring to Figures 4-6, three representative examples of different size optical waveguide lenses 10 of the type depicted in Figure 1 are shown. Each of these three optical waveguide lenses 10 would be suitable for different applications in collimating or focusing a light beam relative to the associated optical waveguide 12, and for the same optical waveguide 12 great variation in the cross-sectional dimensions of the throat portions 16, diameters of the spherical lens portions 18, and overall or combined lengths of the lens members 14 may be achieved.

For example, in Figure 4 an optical waveguide 12 having a diameter of approximately $125\ \mu\text{m}$ is fused to a throat portion 16 having a cross-sectional dimension of approximately $200\ \mu\text{m}$. The spherical portion 18 of the lens member 14 has a diameter of approximately $400\ \mu\text{m}$, and the mode field diameter of the projected beam is approximately $50\text{-}100\ \mu\text{m}$ measured at the beam waist. In Figure 5, the spherical portion 18 of the lens member 14 has a diameter on the order of $1\ \text{mm}$, and the mode field diameter of the projected beam is approximately $100\text{-}250\ \mu\text{m}$ measured at the beam waist. In Figure 6 the throat portion 16 of the lens member 14 has a cross-sectional dimension of between $200\text{-}300\ \mu\text{m}$, and the spherical portion 18 of the lens member 14 has a diameter on the order of $2\ \text{mm}$. The mode field diameter of the projected beam is greater than $300\ \mu\text{m}$ measured at the beam waist, and optical waveguide lenses 10 having beam waists of $800\text{-}1000\ \mu\text{m}$ can be fabricated for desired applications.

Referring to Figure 7, the elements of the optical waveguide lens 10 are shown diagrammatically. Previously, the volume of the optical waveguide lens 10 was approximated by the combined volume of a sphere having a radius equal to the radius of curvature R_C of the lens surface plus a cylinder having a diameter equal to the cross-sectional dimension of the throat portion 16. However, this first-order approximation is slightly incorrect and overestimates the volume of glass required for the lens member 14, as it does not account for the double-inclusion of the volume defined by the truncated spherical secant section (shown in phantom lines) representing the overlap between the sphere and cylinder. Conversely, if the cylinder is assumed to be tangent to the sphere, the first-order approximation of the volume of the lens member 14 does

not include the volume of glass filling in the region between the face of the cylinder and the surface of the sphere around the tangent point, thus underestimating the volume of glass required to fabricate the lens member 14. A second-order approximation of the volume of the lens member 14 omitting the double-inclusion of the overlapping volume is easiest to calculate, but such an estimation including the tangential fill area could also be calculated for a lens member 14 having an overall or total length L_T .

Referring to Figure 8, the optical waveguide lens 10 is again shown diagrammatically, and it will be appreciated that in simplified terms when the optical waveguide lens serves as a collimator the light beam 26 expands as it emerges from the core 28 of the optical waveguide 12, continues to expand via Gaussian diffusion as it passes through the throat portion 16 and spherical portion 18 of the lens member, refracts at the spherical surface 30 of the lens member 14, and then converges towards the beam waist. When the optical waveguide lens 10 serves as a focusing lens, the light beam 26 traverses the lens member 14 in the opposite direction or path, with the beam diameter focusing or decreasing rather than expanding.

Referring to Figure 9, a pair of optical waveguide lenses 10 are shown diagrammatically, each of the optical waveguide lenses 10 disposed on opposing sides of an optical device 32 such as a thin-film filter. The light beam 26 is expanded and collimated by one of the optical waveguide lenses 10, propagates through free space before interacting with the optical device 32 disposed approximately at the beam waist of the light beam 26, similarly propagates through free space to the opposing optical waveguide lens 10, and is focused by that optical waveguide lens 10 to the core 28 of the opposing optical waveguide 12. If the optical device 32 is only partially transmissive, a portion of the light beam 26 propagates through the optical device 32 as described, with the remaining portion of the light beam 26 being reflected back to the original optical waveguide lens 10. The surface 30 of the optical waveguide lenses 10 may therefore include an antireflective coating preventing or minimizing the portion of any undesirable backreflected light beam 26 which enters the optical waveguide lens 10 and is focused on the optical waveguide 12.

Referring to Figures 10-15, a first embodiment of the process for fabricating the optical waveguide lens 10 of the present invention is shown diagrammatically. In Figure 10, an optical waveguide 12 of the type selected for the optical waveguide lens

10 is gripped and positioned using a micropositioning stage (not shown) in the desired alignment with a lens blank 34. The lens blank 34 may be of any suitable length and cross-sectional shape, with a cylindrical embodiment being shown in Figure 10. The lens blank 34 is similarly gripped and positioned using a micropositioning stage, with one or both of the optical waveguide 12 and lens blank 34 being moveable in the X, Y, and Z directions as well as angularly relative to one another. The optical waveguide 12 and lens blank 34 are moved into close confronting proximity or contact with one another, and in the vicinity of arc fusion splicer filaments 36 or a similar heating source, as shown in Figure 11. Heat is applied and the optical waveguide 12 and lens blank 34 contact and are pressed against one another until fused together at the junction 20. The optical waveguide 12 and lens blank 34 are then backed off (or the arc fusion splicer filaments 36 are moved, or both), to a desired or predetermined location along the lens blank 34 as shown in Figure 12. This position is determined based upon a first or second order estimate of the desired geometric volume of the final lens member 14 being fabricated. The lens blank 34 is heated and the portions on opposing sides of the arc fusion splicer filaments 36 are tensioned to draw and separate the lens blank 34 into two segments each having tapered ends 38 as shown in Figure 13, one segment of which is the lens blank 34 attached to the optical waveguide 12, and the remaining segment 40 is held by the micropositioning stage and may be connected to a supply of lens blank 34 material. The tapered end 38 of the remaining segment 40 may be scored and separated to produce a clean end face and a new lens blank 34 to be used to fabricate a further lens member 14 on another optical waveguide 12.

The tapered end 38 of the lens blank 34 is then positioned proximate to the arc fusion splicer elements 36 as shown in Figure 14, and heat is applied to the tapered end 38 of the lens blank 34 sufficient to raise the tapered end 38 of the lens blank 34 to or above its softening point, whereby the tapered end 38 of the lens blank 34 and a portion of the cylindrical lens blank 34 soften and melt sufficiently so that the surface tension of the viscous glass material forms the generally spherical portion 18 of the lens member 14, which is allowed to cool and results in the formation of a lens member 14 having a spherical portion 18 and a throat portion 16 as shown in Figure 15, with the lens member 14 being integrally attached to the optical waveguide 12 to form the optical waveguide lens 10.

It will be appreciated that the tapered end 38 of the lens blank 34 may be approximated as having a volume equal to the sum of a truncated cone plus half a sphere, and the entire lens blank 34 attached to the optical waveguide 12 will have a volume approximated as a cylinder plus a truncated cone plus half a sphere. This volume would then be equal to the volume of the resulting lens element 14. These geometric volumes may thus be utilized in estimating the position of the lens blank 34 relative to the arc fusion splicer elements 36 or other heat source applied to the lens blank 34 to separate the lens blank 34 from the remaining segment 40. Depending upon the type and power of the heat source, the physical dimensions of the lens blank and resulting lens member 14, and characteristics of the glass material including its softening point, viscosity, and surface tension, a degree of variation in these dimensions will result, and proper and reproducible positioning of the lens blank 34 relative to the arc fusion splicer elements 36 or other heat source to fabricate precisely the desired lens length and radius of curvature will be achieved by empirical sampling.

Because the power requirements and heating times for fabricating the optical waveguide lens 10 are greater than those for splicing conventional silica optical fibers, it has proven suitable to use an arc fusion splicer employing slightly oversized or high-power electrodes to enhance their useful life, or a tungsten filament loop splicer rather than an arc fusion splicer. One example of the latter is a Vytran FFS-2000 splicer using a 15 ampere DC power supply. In such a case, the filament housing may be purged with argon or an argon-containing atmosphere at about 0.5-1.0 liters per minute or greater to prevent tungsten oxidation. A heating element having a shape closely conforming to the finished shape or surface of the lens member 14 may be utilized in the melt-back stage of forming the spherical portion 18 of the lens member 14.

Another approach is to use a CO₂ laser as the heat source, with the beam being separated into four portions which converge on the optical waveguide 12 and lens blank 34 from four circumferentially spaced-apart directions to uniformly heat the target area of the lens blank 34.

It has proven suitable to use a lens blank 34 fabricated from a glass material having a softening point lower than the core 28 of the optical waveguide 12. In a representative example of a standard single-mode optical waveguide 34 such as SMF-

28 optical fiber available from Corning Incorporated of Corning, New York, the core 28 is a germania-doped silica.

One glass material which has proven suitable for use as the lens blank 34 in forming the lens member 14 of the optical waveguide lens 10 of this invention is a borosilicate glass, particularly a silica glass doped with 4 mole percent (mol%) of B_2O_3 , conventionally referenced as 4 mol% B_2O_3 - SiO_2 glass. The borosilicate glass splices well to standard single-mode fibers and other optical waveguides 12, and produces uniform and reproducible lens members 14 with select rates above 90% for a working distance of 4 mm. The use of borosilicate glass improves performance because fusion splicing a silica optical waveguide 12 with a borosilicate glass lens blank 34 causes thermal core broadening (i.e., on the order of 31% for splicing to either SMF-28 or large-effective-area non-zero dispersion shifted optical waveguides 12), which enlarges the mode field diameter and increases the tolerance for lateral misalignment of the optical waveguide 12 to the lens blank 34. Angular alignment must be closely controlled. A comparison of the filament powers used in the fabrication steps described above as between silica, germania-doped silica, and borosilicate glasses is instructive. As one representative example, in the process described above where splicing the optical waveguide 12 to a silica lens blank 34 will require 20-21 watts of filament power or 19 watts for germania-doped silica, only 18 watts are required for borosilicate glass. In taper cutting the lens blank 34, the corresponding figures are 26 watts for silica, 24 watts for germania-doped silica, and 21 watts for borosilicate glass. In melt back to form the spherical lens portion 18, the corresponding figures are 31 watts for silica, 26 watts for germania-doped silica, and 24 watts for borosilicate glass. Standard properties of the borosilicate glass include a softening point of 1520 °C, an n_D of 1.457, α of $9 \times 10^{-7} \text{ deg}^{-1}$, an annealing temperature of 999 °C, strain point of 910 °C, elasticity of 9.2×10^6 psi, α of $4.6 \times 10^{-7} \text{ deg}^{-1}$ at the strain point, $\ln \eta_0$ of -8.793 poise (where η_0 is viscosity at infinite temperature), and Q (activation energy divided by gas constant) of 49520 (K). A plot of viscosity as a function of temperature shows that borosilicate glass has a slope less than that for silica, allowing the use of lower temperatures for fabricating the optical waveguide lens 10 of the present invention.

Referring to Figures 16-18, a method for mounting the optical waveguide lens 10 of the present invention in a ferrule 42 is shown. The ferrule 42 may be any

conventional ferrule 42 of the type used in fabricating optical components, fabricated from glass, ceramic, glass-ceramic, or metal. The ferrule 42 may have a flat, conical, or concave front surface (not shown). The ferrule 42 defines a bore 44 through which the optical waveguide 12 is inserted, such that the distal tip of the optical waveguide 12 extends sufficiently from the ferrule 42 as shown in Figure 16. A lens blank 34 is fused to the optical waveguide 12, and a lens member 14 is formed as shown in Figure 17. The optical waveguide 12 is then retracted through the bore 44 of the ferrule 42 until a portion of the lens member 14 contacts and is seated against the front face of the ferrule 42 (or alternately seated partially or totally within a recess defined in the front face of the ferrule 42), and the lens member 14 is secured to the ferrule using an adhesive or other suitable fastening or mounting technique as shown in Figure 18.

Referring to Figures 19-21, an automated method for fabricating a lens member 14 having an integral mounting post 46 is depicted which utilizes the processes of the present invention. A lens blank 34 of a continuous feed stock of glass material is provided, the distal end of which is heated to form a generally spherical lens member 10 as shown in Figure 21. The lens blank 34 is then heated and separated at a position remote to the lens member 10, to form the lens member 10 having an integrally formed mounting post 46 extending therefrom. The lens member 10 is mounted by securing the mounting post 46 in a suitable substrate 48 or other fixture at the position and orientation desired for operation, such that a light beam 26 will propagate through the lens member 10 at an angle generally perpendicular relative to the orientation of the mounting post 46.

Referring to Figure 22, a representative example of an optical component such as a multiplexer fabricated using a plurality of the optical waveguide lenses 10 of the present invention is shown. It is understood that this diagrammatic depiction is not to scale, and that the propagation of the light beams 26 is representative of function only. In the multiplexer, a pair of the optical waveguide lenses 10 are each spaced apart and optically connected to parallel input waveguides 12, through each of which propagates a different wavelength of light λ_1 , λ_2 respectively. The light beams 26 may each have different optical properties preselected or predetermined for the function of the optical component, for example orthogonal polarizations. The light beams 26 are expanded and collimated, and propagate from each of the optical waveguide lenses 10 through

free space into a birefringent element 50 which acts on each of the light beams 26 in a characteristic manner, such as by causing a refractive angular shift of one polarization but not the other. In the exemplary multiplexer, the birefringent element 50 causes the light beams to converge towards one another, and exit the opposing face of the birefringent element 50 and propagate through free space to a third optical waveguide lens 10 whereat both light beams 26 for the two wavelengths of light λ_1 , λ_2 are focused onto a common optical waveguide 12. Such a multiplexer may be utilized for combining a transmission signal at one wavelength λ_1 from a first input waveguide 12 with a pump laser source from a second input waveguide 12 at another wavelength λ_2 onto a common output waveguide 12 carrying both wavelengths λ_1 , λ_2 .

It will be apparent to those skilled in the art that various modifications and variations can be made to the present invention without departing from the spirit and scope of the invention. Thus, it is intended that the present invention cover the modifications and variations of this invention provided they come within the scope of the appended claims and their equivalents.
